An unusually large Kadowaki–Woods ratio of $A_{c2} \gamma^2 \sim 43 \mu \Omega\text{cm}\cdot\text{mol}^2\cdot\text{K}^{-2}$ has been observed for intermetallic Mn$_{1-x}$Fe$_x$CoGe compounds in the proximity of $x=0.2$ where the magnetic state of itinerant electrons system changes. The ratio is approximately four times larger than observed for heavy fermion systems. The manifestation of the strong electron correlations can be realized from the anisotropic origin of the effect through the substantial reduction of interlayer transport of heavy quasiparticles with comparable mean-free path and interlayer spacing in the proximity of a noncollinear ferromagnetic state associated with a large density of states at the Fermi level. © 2013 AIP Publishing LLC.

A central issue regarding the physics of strong electron correlations is the interplay between the itinerancy of electrons in solids due to wave function hybridization and localizing effects that are often rooted in electron-electron repulsion.\textsuperscript{1,2} As a result of these competing interactions, strongly correlated electron systems (SCES) exhibit a wide range of fascinating physical properties, such as heavy fermion behavior, metal-insulator transitions, high temperature superconductivity, colossal magnetoresistance, and so on.\textsuperscript{1,2} According to Fermi-liquid theory, for metallic systems the quadratic term of the resistivity, $\rho(T) = \rho_0 + A T^2$, is associated with electron-electron scattering at low temperature, and the electronic heat capacity varies linearly with temperature ($C_\text{el} = \gamma T$). Therefore, the $A_{c2} \gamma^2$, defined as the Kadowaki–Woods ratio (KWR), can be estimated from low-temperature zero-field resistivity and heat capacity. The KWR is material specific, and can vary strongly with different classes of materials. Relatively small values of $A_{c2} \gamma^2 \sim 0.4 \mu \Omega\text{cm}\cdot\text{mol}^2\cdot\text{K}^{-2}$ have been reported for transition metals.\textsuperscript{3} However, a large KWR has been observed in various types of SCES, such as heavy fermions (where $A_{c2} \gamma^2 \sim 10 \mu \Omega\text{cm}\cdot\text{mol}^2\cdot\text{K}^{-2}$),\textsuperscript{4} transition metal oxides,\textsuperscript{5,6} organic charge-transfer salts,\textsuperscript{7,8} and has been recently observed in high T$_c$ superconductors based on FeAs.\textsuperscript{9} Several physical mechanisms have been proposed for explanation of the large KWR observed in the SCES. A unified model of KWR based on the dimensional analogy has been recently proposed in Ref. 10. It has been shown that the anisotropic transport of heavy quasiparticles (QP) in layered materials, such as transition-metal oxides and organic charge-transfer salts, can give rise to a large KWR. However, in the case of strongly correlated intermetallic compounds, the observation of a large KWR due to an anisotropic origin is rather uncommon. In this letter, we show that the large KWR observed in intermetallic Mn$_{1-x}$Fe$_x$CoGe compounds can be related to anisotropy of the strong electron correlations.

In recent years, considerable attention has been devoted to studies of MnCoGe-based systems due to temperature induced magnet-structural transitions resulting in shape memory phenomena, the giant magnetocaloric effects, and volume anomalies near room temperature.\textsuperscript{11,12} It is therefore of interest to conduct a deeper study of these systems perhaps to elucidate the physical origins of their pronounced physical properties. In particular, the rarely studied experimental electronic properties of MnCoGe-based systems may shed light on the behavior of this system. In fact, the major outcome of our experimental work suggests that Mn$_{1-x}$Fe$_x$CoGe in the vicinity of $x=0.2$ can be considered as a strongly correlated metal.

According to neutron diffraction studies, stoichiometric MnCoGe and FeCoGe both have a collinear magnetic structure in the basal plane, and behave as an isotropic ferromagnet below their respective Curie temperatures of $T_C \sim 345$ and 370 K.\textsuperscript{13} MnCoGe has an orthorhombic TiNiSi-type structure in the ferromagnetically ordered state, but transforms to a hexagonal Ni$_2$In-type structure in the paramagnetic (PM) state at about $T_M \sim 650$ K. However, FeCoGe crystallizes in a hexagonal phase which is stable in the entire temperature interval. Studies of isostructural MnNiGe-based systems indicate that an alternating sequence of Ni-Ge and Mn layers perpendicular to the c-axis is formed in its hexagonal phase.\textsuperscript{14} A larger magnetic moment has been reported for the orthorhombic structure in comparison with that of the hexagonal phase, which is associated with the localized narrower 3$d$ band in the orthorhombic structure and a wider 3$d$ band in the hexagonal structure, resulting in itinerant character due to the decrease in bond length.\textsuperscript{15} Therefore, the substitution of Fe atoms for Mn in Mn$_{1-x}$Fe$_x$CoGe can stabilize the hexagonal structure at lower temperature with a reduced magnetic moment. It has been shown in Ref. 16 that, in the case of CoMnX (X = P, Si, Ge), the collinear ferromagnetic (FM) phase with a high density of the electronic states is unstable compared to that in the noncollinear phase (anti-ferromagnetic or FM). A high number of states promotes a noncollinear magnetic arrangement in these types of compounds.\textsuperscript{16,17} The calculated total density of the states ($D_0(E_F)$) was found to be $D_0(E_F) = 5$ states/eV/f.u. for the parent MnCoGe.\textsuperscript{16} Therefore, a more than three-fold increase in $D_0(E_F)$ as estimated for Mn$_{0.8}$Fe$_{0.2}$CoGe from the experimental results of the current work implies the...
existence of a noncollinear FM state in the hexagonal layered compound which results in the formation of massive QP. Our studies reveal an unusually large KWR of $\Delta|t|^2 \sim 43 \mu\Omega\text{cm-mol}^2\text{K}^2\text{J}^{-2}$. Therefore, strong electron correlations in the Mn$_{1-x}$Fe$_x$CoGe system can be associated with the anisotropic interlayer transport of heavy QP in the proximity of the changes in magnetic state of the itinerant electrons system induced by the increase in Fe concentration. The obtained results are explained in the context of a unified model of KWR.

Polycrystalline Mn$_{1-x}$Fe$_x$CoGe samples were prepared by arc-melting the constituent elements of purity better than 99.99% in an ultra high purity argon atmosphere using water cooled massive bronze crucible and tungsten electrode, followed by annealing in high vacuum ($\sim 10^{-5}$ Torr) for 4 days at 850°C. The room temperature X-ray diffraction patterns of the samples were obtained using Cu Kα radiation. Structural refinement was carried out using the Rietveld profile refinement method of the FULLPROF program. A superconducting quantum interference device magnetometer (SQUID, by Quantum Design, INC.) was employed to measure the magnetization of the samples within the temperature interval of 10–400 K, and in applied magnetic fields up to 5 T. The samples were heated to 380 K prior to magnetic measurements. The phase transitions temperatures, $T_C$ and $T_M$, were determined from the maximum of $dM/dT$ measured during heating in the presence of 1 kOe magnetic field. The saturation magnetizations ($M_S$) were obtained by extrapolating the high-field $M(H)$ data to zero field at $T = 10$ K. The differential scanning calorimetry (DSC) measurements were carried out with a DSC 8000 (with a ramp rate of 20 K/min during heating and cooling). Heat capacity ($C_P$) measurements were done using a physical properties measurement system (PPMS by Quantum Design, INC.) using a vertical puck arrangement. Electrical resistivity ($\rho$) measurements were performed using the standard four-probe method.

The X-ray diffraction patterns of Mn$_{1-x}$Fe$_x$CoGe as shown in Figs. 1(a)–1(c) confirm the hexagonal Ni$_2$In-type structure for $x > 0.09$ at room-temperature, except for small traces of the orthorhombic TiNiSi-type structure for $x = 0.09$. The composition-dependent hexagonal lattice parameters $a$ and $c$ both decrease with increasing Fe concentration. According to the literature, with a smaller Mn-Mn separation, the MnCoGe-based system prefers to stabilize in the hexagonal phase. Therefore, the reduction of the Mn-Mn distance associated with the decrease of lattice parameters by the substitution of smaller Fe atoms for Mn, stabilizes Mn$_{1-x}$Fe$_x$CoGe in the hexagonal Ni$_2$In-type structure. A linear decrease of $c(x)/a(x)$ has been observed as shown in Fig. 1(d). However, the relative changes in $c$ are more significant than those of $a$. For composition variations of $x = 0.09–0.4$, the lattice parameters decrease almost linearly from 4.095 to 4.080 Å and from 5.296 to 5.208 Å for $a$ and $c$, respectively. Therefore, $c$ decreases more rapidly compared to that of $a$, resulting in a decrease of $c/a$ ratio associated with a smaller Mn-Mn/Fe separation along c-axis with increasing substitution of Fe. This indicates that Fe-substitution leads to a substantial reduction of the interlayer distance of Mn/Fe atoms as separated by a Co–Ge layer perpendicular to the c-axis. An alternating sequence of Co-Ge and Mn layers in the MnCoGe-based systems are shown in the inset of Fig. 1(d).

The variations of the transition temperatures ($T_C$ and $T_M$) with Fe concentration, along with the temperature the peak positions of the DSC heating curves, are shown...
The partial substitution of Mn by Fe in Mn$_{1-x}$Fe$_x$CoGe results in a coincidence of $T_C$ and $T_M$ for low Fe concentrations ($x = 0.09$ and 0.1), leading to a first-order phase transition with a clearly visible thermal hysteresis between heating and cooling in both the M(T) and DSC curves. With a further increase of $x$, a structurally driven first-order phase transition has been observed below $T_C$ up to $x = 0.15$. For $x > 0.2$, a second-order magnetic transition, similar to that observed for the PM-FM transition with the hexagonal Ni$_2$In-type structure, was detected with no signature of a first-order transition. $T_M$ decreases sharply with increasing $x$ and nearly vanishes for $x = 0.15$ with only small traces in the DSC curve. However, an increase of $T_C$ has been observed with increasing $x$. The M(H) curves show a shape typical for FM type ordering (see inset of Fig. 2). The saturation magnetizations ($M_S$) initially decrease with increasing $x$ but remain nearly constant (about 2.8 $\mu_B$/f.u.) in the hexagonal phase for $x / C 0.2$. 

Representative data of the temperature-dependent inverse susceptibility ($\chi^{-1}$) in the presence of 1 kOe for $x = 0.1$ and 0.2 are plotted in Fig. 3(a). In the PM state, the linear variations of $\chi^{-1}(T)$ for small $x$ were well-fitted by the standard Curie-Weiss term, indicating a localized moment behavior. However, a modified Curie-Weiss expression, $\chi = \chi_0 + C/(T - \theta_P)$ (where $\chi_0 = T$-independent susceptibility, $C = $ Curie constant, and $\theta_P = $ PM Curie temperature) was used to fit the nonlinear $\chi^{-1}(T)$ curve for higher Fe concentrations, suggesting a temperature-independent contribution from itinerant behavior. From the fitting, the values of $C$ and $\theta_P$ were obtained for different $x$. The effective magnetic moment ($\mu_{eff}$) was determined from the Curie constant $C$. According Rhodes-Wohlfarth model, a value of $P_C/M_S$ (where $P_C = $ total spin angular moment and $P_C(P_C + 2) = \mu_{eff}^2$) greater than the unity implies an itinerant moment system. Therefore, a large $P_C/M_S \sim 2.2 \mu_B$/f.u. for $x \geq 0.2$ (see Fig. 3(b)) indicates a significant contribution due to itinerant magnetic behavior of the Mn$_{1-x}$Fe$_x$CoGe compounds. A hydrostatic pressure study on the MnCoGe-based system also indicated an itinerant character of the 3d-subsystem in these types of compounds. Thus, Fe in Mn$_{1-x}$Fe$_x$CoGe intermetallics generally contributes to the itinerant component of the 3d-subsystem.
from the β value is 306 K. The DOS at E_F estimated from the γ value is D_0(E_F) = 16.5 states/eV/f.u. Previously it has been shown that, in the case of the CoMnX (X = P, Si, Ge), the noncollinear ground states (antiferromagnetic or ferromagnetic) are energetically preferable compared to the collinear FM phase as characterized by the low total density of states at the Fermi level, D_0(E_F). A high number of states can make the collinear FM state unstable and promotes a noncollinear magnetic arrangement in these types of compounds.16,17 Therefore, a more than three-fold increase in D_0(E_F) for Mn_{0.8}Fe_{0.2}CoGe relative to that of the parent MnCoGe (D_0(E_F) = 5 states/eV/f.u.) suggests the instability of the collinear FM state in this composition and promotes a stable noncollinear FM state. A noncollinear magnetic state can be stabilized in any elements, alloys, or compounds through the formation of a hybridization gap at the Fermi energy, as emphasized previously, and was recently found the related system CoMnSi.16,17

The temperature dependence of the resistivity (ρ) in the absence of magnetic field is shown in Fig. 4(b) for the compounds with x = 0.2 and 0.4. The ρ(T) data suggest metallic ground states for both compositions. A rather large residual resistivity for x = 0.2 (ρ_0 = 624 μΩ cm) compared to most conventional metallic conductors seems to be related to interlayer transport associated with a substantial reduction of the mean-free path of heavy quasiparticles. As mentioned previously, the compositions for x ≥ 0.2 have a stable hexagonal Ni_2In-type structure without a first-order structural transition. An alternating sequence of Co-Ge and Mn layers perpendicular to the c-axis is formed in hexagonal structure of MnCoGe as reported earlier on isostructural hexagonal MnNiGe-based systems. A change of slope has been observed in ρ(T) in the vicinity of T_C. The low-temperature ρ(T) data for x = 0.2 was fitted by ρ(T) = ρ_0 + AT^2, suggesting a dominant electron-electron scattering behavior (see the inset of Fig. 4(b)). The value of A obtained from the fit is 0.0324 ± 0.0002 μΩ cm K^-2. Therefore, the Kadowaki–Woods ratio for x = 0.2 is KWR = A/β^2 ≈ 43 μΩ·cm·mol^2 K^-2·J^-2. This value is much larger than the value A/β^2 ~ 10 μΩ·cm·mol^2 K^-2·J^-2 reported for a number of heavy fermion compounds, suggesting that Mn_{0.8}Fe_{0.2}CoGe is a strongly correlated metal. Although the studied materials were synthesized from isotropic end-members (MnCoGe and FeCoGe) similar to that of heavy fermion compounds, the development of strong electron correlation in Mn_{0.8}Fe_{0.2}CoGe has an unexpected and unique anisotropic origin. In this case, interlayer transport of heavy QP due to the formation of a layered structure is the origin of the strong electron correlation. This will be explained in the context of the unified model developed recently by Jacko et al.10 to describe the KWR by considering a dimensional analysis.

The model by Jacko et al. employs a normalized KWR in the form of A_{k_F}(n)β^2 = 81/4nℏν_0c^2, according to which a broad class of strongly correlated metals takes a single value. In this KWR, A_{k_F}(n) represents the dimensional term (d = dimensionality) with f_0(n) = nD_0^2(ν_0^2/2)^2, where n, D_0, and (ν_0^2/2) represent the conduction-electron density, the DOS at E_F, and the Fermi velocity, respectively, and ⓐ = 1 is a pure number. For anisotropic layered materials, (ν_0^2/2) may vary in the different crystallographic directions. In this model, they found for quasi-2D layered materials that f_0(n)β^2 = n^2/nℏc^2 (c = interlayer spacing) and f_0(n)β^2 = 2nD_0^2(ν_0^2/2)^2/ℏc^2. Notably, the interlayer hopping integral (t_{1,0}) is the most important parameter for layered systems, whether it is via coherent transport or thermally assisted hopping. The above-described formalism fits quite well for reported layer-type SCES, which exhibit large values of A_{k_F}β^2 without considering f_{k_F}(n), and becomes single-valued after the addition of f_{k_F}(n). In other words, the relatively small value of f_{k_F}(n) is solely responsible for the large A_{k_F}β^2 observed in layered SCES. Therefore, the substantial reduction of t_{1,0} due to the decrease of interlayer QP transport makes f_{k_F}(n) (i.e., effectively f_{k_F}(n)) small, and enhances the A_{k_F}β^2 value for layered SCES. At 300 K, the measured ρ are 1399 and 518 μΩ cm for x = 0.2 and 0.4, respectively. These correspond to a normalized mean-free path of k_F ≈ h(κ/2)e^2/ℏc ≈ 0.5 and 1.3 along the direction perpendicular to the atomic layers with c = 5.28 and 5.22 Å for x = 0.2 and 0.4, respectively (where c = lattice constant along c-axis, κ = interlayer spacing of atomic planes of Mn or Mn-Fe, and h/ℏ^2 ≈ 26 Ω is the quantum resistance), which suggest a higher degree of metallicity for the composition with x = 0.4 compared to that of x = 0.2. The substantial reduction of k_F decreases it comparable with c/2 in the proximity of the noncollinear FM state for x = 0.2. As a result, the interlayer QP transport (t_{1,0}) at low temperature decreases markedly, which ensures that it becomes a SCES with large A_{k_F}β^2 for x = 0.2 due to the substantial decrease of the effective f_{k_F}(n). Moreover, it would be reasonable to anticipate that a large D_0(E_F) should result in a narrower effective bandwidth (W = 4t_{1,0}) for x = 0.2, and therefore t_{1,0} should be reduced. The system moves towards a collinear FM state having normal 3D metallic behavior (as observed for x = 0.4 with large normalized mean-free path perpendicular to the atomic layers in comparison to x = 0.2) with x > 0.2 after exhibiting a noncollinear FM state for x = 0.2. The trend of the normal metallic behavior for higher Fe concentrations is well supported by the collinear behavior reported for FeCoGe. Transport and neutron diffraction studies on a single crystal sample would be beneficial to understand the unusual type of strong electron correlation in this system, and will be a topic of future studies.

As explored in this study, a noncollinear stability in a FM material can lead to strong electron correlations. The substantial reduction of interlayer QP transport with a comparable mean-free path and interlayer spacing in the proximity of noncollinear FM state results in a large A_{k_F}β^2 ~ 43 μΩ·cm·mol^2 K^-2·J^-2 in Mn_{0.8}Fe_{0.2}CoGe as consequence of strong electron correlations.
